Introduction

- aerosol sample is drawn from the engine exit plane to the instruments through more than 30 m long sample lines
- particles stick to the tube walls due to diffusional and thermophoretic effects
- first principle model predicts well the particle transport efficiency in terms of particle number concentration
- PM mass losses are more complicated - particle effective density changes with size
- a reliable estimate of the PM at the engine plane essential for the emissions quantification and modeling

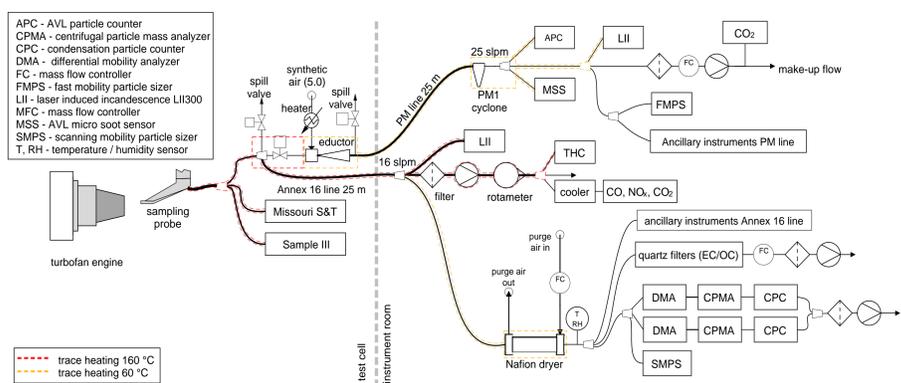

Method

- measure non-volatile PM mass (equivalent / refractory black carbon; BC)
- measure particle size distributions (PSD)
- fit lognormal distributions and find dependence on engine thrust
- determine effective density distributions from mass-mobility measurements
- model the particle transport efficiency from the probe tip to the instruments
- iterate the PM mass derived from the lognormal PSD model and the effective density distributions until it is equal to the measured PM mass
- correct the model PM mass distribution using the inverted penetration function
- calculate the line loss correction factor as a ratio of the corrected and uncorrected (measured) PM mass

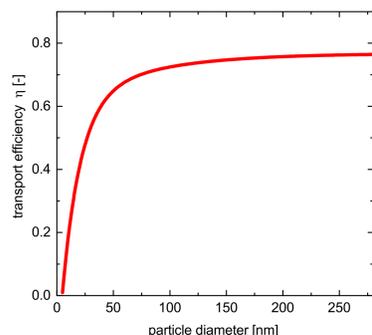

Sampling and measurement

- CFM56-7B26/3 engine (Boeing 737, Airbus A320) tested in an engine test cell over the entire thrust range from idle to maximum power
- primary PM measurements on the diluted line (factor ~10:1; PM line)
- ancillary PM measurements on the undiluted line (Annex 16 line)
- up to 3 systems built to the same standard¹ were deployed in parallel

Particle transport model

- UTRC particle transport tool² uses basic aerosol mechanics theory for particle transport efficiency prediction in the aircraft exhaust sample lines

Results and outlook

- line loss correction factor for PM mass ranged from 2.75 at engine idle to 1.35 at maximum power conditions using the size-dependent effective density
- the unit density assumption provided a similar range of correction factors, but might have overestimated the losses at high thrust as well as underestimated at low thrust
- probe inlet temperature needs to be measured for a more accurate thermophoretic loss prediction
- future work will focus on intercomparison with models that do not use measured effective density and particle size

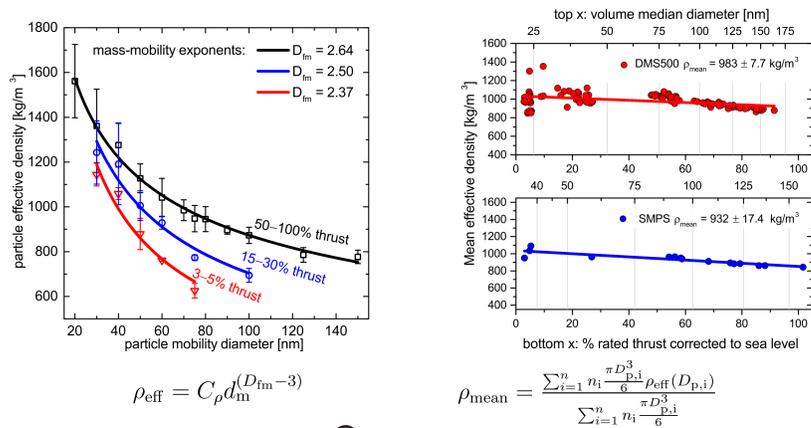

Total PM mass (TPM) and measured BC mass

- TPM calculated from the effective density distributions and PSD agreed with the BC mass measured by the MSS

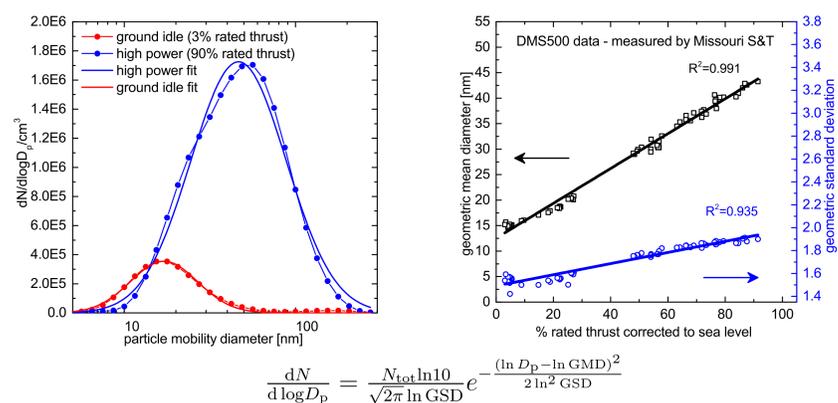

Effective density: distributions and mean

- power law fits of experimental data (CPMA mass over mobility equivalent volume)
- increase with engine thrust: primary particle size growth and change of the internal structure from amorphous to crystalline (Liati et al., 2014, submitted to Env. Sci. Technol.)
- mean effective density decreased with engine thrust (GMD shifted to larger diameter particles that have lower effective density)
- could be approximated as unit density (1000 kg/m³) for this engine

Particle size distribution

- Geometric mean diameter (GMD) and the geometric standard deviation (GSD) determined from the lognormal fits increased linearly with engine thrust
